

SELF REFLECTION

For this assignment, I found it interesting to use GPT-4.1 to perform simple multiplication. The task was to give the AI two integers and ask it to calculate the result. Since multiplication is normally very simple for a computer, I expected the results to be correct most of the time. However, the purpose of the assignment was to show that an AI model can still make mistakes when doing calculations.

I found the comparison between the AI-generated result and the correct result to be the most interesting part. The bot does not simply trust GPT-4.1's answer. Instead, it calculates the correct answer separately and compares both results. If they are the same, the bot recognizes the AI answer as correct. If they are different, the bot can show that the AI made a mistake. This made me think about how AI can sound confident even when the result is not correct.

For my three combinations, I used (5, 15), (7, 10), and (9, 5). These examples were simple, but they were useful for testing whether the bot could receive different inputs and compare the results properly. I also found it interesting that even though the task is very simple, it is still important to have another method to verify the answer instead of assuming that the AI is always correct.

One thing I learned from this assignment is that language models are not always the best tool for tasks that require exact calculations. GPT can understand the question and produce an answer, but that does not necessarily mean the answer is mathematically correct. Using a normal calculation in the program gives the bot a reliable way to check the AI's prediction. I think this is useful because it shows how AI and traditional programming can work together instead of depending completely on the AI.
